Environmental arsenic exposure, through drinking contaminated water, is a significant risk factor for developing vascular diseases and is associated with liver portal hypertension, vascular shunting, and portal fibrosis through unknown mechanisms. We found that the addition of low doses of arsenite to the drinking water of mice resulted in marked pathologic remodeling in liver sinusoidal endothelial cells (SECs), including SEC denervation, capillarization, increased junctional PECAM-1 expression, protein nitration, and decreased liver clearance of modified albumin. Furthermore, the pathologic changes observed after in vivo exposure were recapitulated in isolated mouse SECs exposed to arsenic in culture. To investigate the role of NADPH oxidase-generated ROS in this remodeling, we examined the effect of arsenite in the drinking water of mice deficient for the p47 subunit of the NADPH oxidase and found that knockout mice were protected from arsenite-induced capillarization and protein nitration. Furthermore, ex vivo arsenic exposure increased SEC superoxide generation, and this effect was inhibited by addition of a Nox2 inhibitor and quenched by the cell-permeant superoxide scavenger. In addition, inhibiting either oxidant generation or Rac1-GTPase blocked ex vivo arsenic-stimulated SEC differentiation and dysfunction. Our data indicate that a Nox2-based oxidase is required for SEC capillarization and that it may play a central role in vessel remodeling following environmentally relevant arsenic exposures.

Introduction
Arsenic is a toxic metalloid that constitutes 0.0001% of the Earth's crust and is a common contaminant of drinking water. Drinking arsenic-contaminated water increases risk of cardiovascular disease, lung disease, hepatic disease, and cancer in millions of people worldwide. The World Health Organization and the United States Environmental Protection Agency have set the drinking water standard for arsenic at 10 parts per billion (ppb) based on cancer risk. However, even at this low level, arsenic may increase the occurrence of cardiovascular disease in humans (1-3) and promotes angiogenesis and vascular remodeling in mice (4, 5). Epidemiological studies demonstrate that arsenic increases risk for many vascular pathologies, including peripheral vascular disease, ischemic heart disease, acute myocardial infarction, atherosclerosis, and hypertension (2, 6-8). In addition, vascular remodeling and shunting is commonly observed in arsenic-related liver diseases, such as portal hypertension and noncirrhotic liver fibrosis (9). The pathological mechanisms that contribute to angiogenesis and vascular remodeling in response to arsenic exposures remain unresolved.

Liver sinusoidal endothelial cells (SECs) are unique endothelial cells in both their architecture and their function. The sinusoids are the exchange vessels of the liver, and the SECs are distinguished by extensive fenestrations organized into sieve plates, a lack of a basement membrane, and low junctional expression of PECAM-1 (also known as CD31). The SEC architecture, including open fenestrations and weak junctional association between cells, provides a dynamic filtration system with low perfusion pressure that enables nutrients and macromolecular waste to pass freely to hepatocytes for efficient metabolism. The highly active, clathrin-mediated scavenging system in the SEC contributes significantly to endocytic clearance of waste from blood, including effective removal of pathogenic acylated or glycosylated proteins (10, 11). In addition, the SECs are antigen-presenting cells, and interactions with SECs and underlying hepatocyte microvilli may be important for naive T cell activation (12). Loss of these important SEC functions as a result of age or environmental stresses has been proposed to contribute to risk for systemic vascular diseases as well as hepatic pathogenesis (11, 13, 14).

The maintenance of the SEC phenotype is a critical, but poorly understood, process that requires both autocrine and paracrine cell signaling. Results of recent studies indicate that SEC fenestrations are maintained by constitutive VEGF-stimulated NO generation in the SECs and surrounding cells (15). SEC NO generation, in turn, promotes quiescence of surrounding stellate cells that are profibrotic when activated (16). In response to ethanol (17), oxidizing chemicals (18), surfactants (19), and aging (13), SECs dedifferentiate into a more regular endothelium in a process termed capillarization or pseudocapillarization. The hallmarks of capillarization are SEC denervation, development of a laminin-rich basement membrane, and junctional expression of PECAM. Sinusoidal stellate cells are also induced to overexpress a laminin and collagen matrix that contributes to fibrosis (16). Capillarization precedes the development of many liver diseases, including portal hypertension and liver fibrosis. In addition, loss of...
lipid metabolism or removal of acylated or glycolated proteins following capillarization may enhance atherosclerosis, insulin resistance, and possibly metabolic disease (13, 20, 21). Recently, environmental arsenic exposures (250 ppb) were shown to promote progressive SEC capillarization in intact mice through an unresolved mechanism (22, 23). Superoxide and subsequent ROS generation by Nox-containing NADPH oxidase enzyme complexes in endothelial and smooth muscle cells are fundamental to neovascularization, angiogenesis, and vessel remodeling caused by a variety of endogenous and exogenous factors (24, 25). Arsenic stimulates Nox-based oxidase activity in cultured large vessel vascular cells (26, 27) through mobilization and activation of Rac1-GTPase (26) and increases Rac1 association with SEC membranes during capillarization (22). However, there are no reports of the functional role of this mobilization in capillarization, nor are there reports of a functional role for Rac1-stimulated SEC NADPH oxidase in capillarization in general. In the present study, we investigated the hypothesis that arsenic stimulates SEC Rac1 and oxidase activity to close fenestrations, promote capillarization, and disrupt the physiological function of scavenging modified proteins. The results from the in vivo experiments are the first to our knowledge to demonstrate that low-level arsenic exposures (250 ppb) were shown to promote progressive SEC capillarization in intact mice through an unresolved mechanism (22, 23).

Superoxide and subsequent ROS generation by Nox-containing NADPH oxidase enzyme complexes in endothelial and smooth muscle cells are fundamental to neovascularization, angiogenesis, and vessel remodeling caused by a variety of endogenous and exogenous factors (24, 25). Arsenic stimulates Nox-based oxidase activity in cultured large vessel vascular cells (26, 27) through mobilization and activation of Rac1-GTPase (26) and increases Rac1 association with SEC membranes during capillarization (22). However, there are no reports of the functional role of this mobilization in capillarization, nor are there reports of a functional role for Rac1-stimulated SEC NADPH oxidase in capillarization in general. In the present study, we investigated the hypothesis that arsenic stimulates SEC Rac1 and oxidase activity to close fenestrations, promote capillarization, and disrupt the physiological function of scavenging modified proteins. The results from the in vivo experiments are the first to our knowledge to demonstrate that low-level arsenic exposure stimulates dose-dependent SEC capillarization through activation of p47phox-containing NADPH oxidase enzyme complexes. Ex vivo studies in primary SECs indicated that capillarization was a direct effect of arsenic on the SECs that required Rac1. In addition to identifying a mechanism for the vascular effects of arsenic, our results revealed an essential role for Nox2-based oxidase in the pathogenesis of capillarization.

Results

Arsenic stimulated dose-dependent capillarization and PECAM-1 expression in vivo and ex vivo. Previous studies demonstrated that 250 ppb arsenite in drinking water resulted in progressive SEC defenestration and capillarization that was maximal within 2 wk (23). The threshold for these pathologic changes was below the current maximal containment level of 10 ppb, and loss of porosity was dose dependent between 10 and 100 ppb (Figure 1A). The open dilated fenestrations and numerous sieve plates in control mice were lost, and the arsenite-exposed SECs formed tighter junctions. The loss in porosity was caused by a decrease in both number and size of fenestrations, and, as we have previously reported (22), there was no difference in the degree of arsenic effects between zones 1 and 3 of the sinusoidal beds. Capillarization was confirmed in confocal images of sections stained with anti-PECAM-1, demonstrating a reciprocal dose-response relationship for arsenic-stimulated junctional PECAM-1 expression relative to porosity (Figure 2A). As in previous studies (22, 23), there were no signs of SEC injury or cell death, nor were there any signs of injury in surrounding stellate cells or hepatocytes.

Ex vivo exposure of primary cultured SECs to 1–5 μM arsenite for 8 h recapitulated the in vivo observations, with arsenic causing defenestration and disorganized, consolidated sieve plates (Figure 1B). As seen in vivo, arsenite caused a concentration-dependent increase in junctional PECAM-1 expression as the sieve plates were lost (Figure 2B). These results demonstrate that direct SEC effects may account for arsenite-stimulated capillarization.

Arsenic decreased SEC scavenger receptor function in vivo. A major physiological role of the SECs is scavenging of small macromolecules, such as chylomicron and derivatized plasma proteins (11).
Comparison of liver clearance of biotinylated or FITC-labeled BSA with succinylated BSA was used to examine whether exposure to arsenic functionally impaired SECs. Only the labeled succinylated BSA was taken up in the liver sinusoids relative to labeled native BSA (Figure 3A). Arsenic decreased clearance of biotinylated succinylated BSA by 60% relative to untreated control mice (Figure 3B). A similar decrease was observed in isolated SECs exposed to arsenic ex vivo (Figure 3C). Thus, arsenic-stimulated capillarization was associated with functional loss of physiological scavenging of modified proteins by the SEC.

\( p47^{phox} \) knockout SECs are protected from arsenic-stimulated capillarization. Oxidants and compounds that generate oxidants promote capillarization (13, 18). Because arsenic stimulates NADPH oxidase-derived ROS formation in large vessel endothelial cells (26), we tested whether a similar mechanism mediates arsenic effects in SECs. Mice deficient in the canonical Nox2-based oxidase subunit \( p47^{phox} \) were exposed for 2 wk to 100 ppb arsenic in their drinking water to test the relevance of this oxidase to capillarization in vivo. Controls for these exposures included wild-type and arsenic-exposed mice that were maintained on the same antibiotic and housed on the same bedding as the immunocompromised \( p47^{phox} \) knockouts. We found that sinusoids in the knockout mice did not capillarize in response to arsenic (Figure 4A–C). In addition, ex vivo addition of arsenic failed to decrease porosity in SECs isolated from these knockout mice (Figure 4D). In contrast, addition of \( \text{H}_2\text{O}_2 \) bypassed the lack of oxidase activity in these cells and reduced porosity by 4-fold. The knockout mice were protected from other endpoints of capillarization, such as forming a basement membrane and increased hepatocyte microvilli in response to arsenic (Figure 4C). Finally, arsenic-increased nitration of sinusoidal proteins, an indicator of peroxynitrite formation, was absent in the exposed \( p47^{phox} \) knockout mice (Figure 5). These results demonstrate that superoxide and \( \text{H}_2\text{O}_2 \) generated by \( p47^{phox} \)-containing NADPH oxidase contributed significantly to capillarization.

SEC Nox2 oxidase activity is necessary and sufficient to mediate arsenic-induced capillarization. Primary SECs in culture were exposed to arsenite ex vivo to address whether SEC NADPH oxidase activity was sufficient to mediate the effects of arsenic on SEC function and capillarization. First, SECs loaded with superoxide-sensitive dihydroethidium increased their fluorescence, as measured by hydroethidium formation, within 30 min of arsenic exposure (Figure 6). This increase followed the same concentration dependence as decreased porosity (Figure 1) and increased junctional PECAM-1 expression (Figure 2). Preincubation of the cells with the superoxide scavenger 4-hydroxy-2,2,6,6-tetramethylpiperidine 1-oxyl (tempol) prevented arsenite-increased hydroethidium fluorescence (Figure 6), prevented loss of scavenging function (Figure 3C), and both decreased porosity and increased junctional PECAM-1 expression (Figure 7). Likewise, preincubation
of the cells with gp91ds-tat peptide (an inhibitor designed to disrupt Nox2-based oxidase protein complexes; ref. 28), but not the scrambled-tat control peptide, prevented the arsenite-stimulated superoxide generation and morphologic change (Figures 6 and 7). These results from isolated SECs, combined with the results from research article scrambled-tat control peptide, prevented the arsenite-stimulated superoxide generation and morphologic change (Figures 6 and 7). The current studies focused on a unique form of vascular remodeling, sinusoidal capillarization, that is known to the SEC plasma membrane during capillarization in vivo (22), but the function of this mobilization was unknown. Therefore, the role of Rac1 in arsenic-induced capillarization was tested by examining the effects of a chemical inhibitor of Rac1, NSC23766 (29), on arsenic-stimulated defenestration. Overexpression of Rac1 in arsenic-stimulated SECs was assessed by western blotting in the absence or presence of 1 mM tempol (22, 23). Our present results provide support for an arsenic-stimulated mechanism that requires Nox2-based oxidase-generated oxidants to defenestrate and capillarize SECs as well as impair their physiological functions. In addition, this study is the first to our knowledge to demonstrate a functional consequence of this oxidase activity in SEC capillarization, a process that has been proposed to be oxidant mediated (18, 21). The potential public health implications of these findings are that they suggest that stimulation of Nox2-based oxidase in the SECs, and perhaps other vascular beds, is a fundamental mechanism for the etiology of arsenic-promoted hepatic and systemic vascular diseases.

There have been few reports of a direct physiologic or pathophysiologic role of SEC oxidase enzymes. Several studies demonstrated that oxidants, surfactants, and oxidizing conditions in aging promote capillarization to alter circulating lipid and lipoprotein profiles (13, 18, 19). However, the mechanisms for SEC oxidant generation other than direct chemical action were not investigated in these studies. In rats, high-level ethanol perfusions stimulate SEC capillarization and remodeling (22, 23). Our present results provide support for an arsenic-stimulated mechanism that requires Nox2-based oxidase-generated oxidants to defenestrate and capillarize SECs as well as impair their physiological functions. In addition, this study is the first to our knowledge to demonstrate a functional consequence of this oxidase activity in SEC capillarization, a process that has been proposed to be oxidant mediated (18, 21). The potential public health implications of these findings are that they suggest that stimulation of Nox2-based oxidase in the SECs, and perhaps other vascular beds, is a fundamental mechanism for the etiology of arsenic-promoted hepatic and systemic vascular diseases.

Figure 3
Arsenic inhibits SEC scavenging of acylated protein. (A) Mice were injected in the tail vein with 150 mg/kg FITC-labeled succinylated BSA (succ-BSA) or BSA (both green) in 200 μl saline. After 10 min, the mice were euthanized, and livers were excised, fixed in 4% paraformaldehyde, and stained for confocal microscopic analysis. Sections were stained with rhodamine-conjugated antibody to PECAM-1 (red) and DRAQ5 (blue). Images are representative of sections from 3 mice in each group. LV, large vessel; S, sinusoid vessel. Scale bar: 10 μm. (B) FITC-labeled acetylated LDL and biotin-labeled succinylated BSA (3 ml; 150 mg/ml saline) were infused over 3 min into the vena cava of untreated mice and mice exposed to 100 ppb arsenic (As) for 2 wk. Livers were then excised, frozen in liquid N<sub>2</sub>, and sectioned, and total protein was extracted for assay of retained biotin label by immunoblotting, as described in Methods. Data are mean ± SD band density of biotin-labeled succinylated BSA normalized to β-actin (n = 3), NT, not treated. (C) Isolated SECs, incubated in the absence or presence of 1 mM tempol for 10 min, were left untreated or exposed to 2.5 μM arsenite for 24 h. Biotin-labeled succinylated BSA (20 μg/ml) was then added for 10 min, and after rinsing, total proteins were extracted for Western analysis (n = 3). Data are presented as in B. *P < 0.05, **P < 0.01 versus control; *P < 0.05 versus arsenic.
Figure 4
NADPH oxidase is required for arsenic-stimulated capillarization in vivo. (A) Matched wild-type and p47phox knockout C57BL/6 mice were untreated or exposed to 100 ppb arsenite in their drinking water for 2 wk. Liver sections were imaged by scanning EM at x7,500 magnification. (B) Porosity of liver sections in A was quantified as in Figure 1. Data are mean ± SD; significance of differences was determined by ANOVA followed by Newman-Keuls post test (n = 3 mice per treatment). (C) Representative transmission EM images of liver sinusoids captured from ultrathin sections of mice in A. L, sinusoidal lumen. (D) SECs isolated from p47phox knockout mice were exposed ex vivo to either 2.5 mM arsenic or 50 mM H2O2 for 8 h. The cells were then fixed and imaged by scanning EM, and porosity was quantified as in Figure 1. Data (mean ± SD) indicate percent porosity of 5 separate cultures per group. **P < 0.01 versus control; P < 0.01 versus arsenic. Scale bars: 1 μm (A); 0.1 μm (C).

have demonstrated that there was no increase in inflammatory cells in the livers of mice exposed for 2 wk to the higher arsenic dose of 250 ppb (23). Since arsenic-induced defenestration is fully manifested within 2 wk, these data suggest that arsenic directly affects the SECs or surrounding cells to induce capillarization rather than a through a mechanism requiring leukocyte oxidase activity. In the current study, we used 2 independent strategies to test whether activating SEC Nox2 oxidase was necessary and sufficient to effect phenotype change. First, p47phox is a canonical, essential cytosolic subunit of Nox2-based oxidase, and our results demonstrated that genetic deletion of this subunit prevented arsenic-stimulated sinusoidal generation of nitrotyrosine (Figure 5), loss of porosity (Figure 4A), and morphological changes in the space of Disse (Figure 4C). Nitrotyrosine staining colocalized with PECAM-1-positive SECs. Because superoxide is not capable of crossing cell membranes, our observation suggested that the SECs were the source of superoxide or other reactive intermediates required to react with NO to form peroxynitrite. Second, isolated SECs from wild-type or p47phox knockout mice were used to confirm that Nox2-based oxidase generated superoxide in response to arsenic exposure and that this superoxide or its derivatives was sufficient to cause the morphological changes indicative of capillarization. Arsenic failed to decrease porosity of cells that were genetically deficient in Nox2-based oxidase activity, and decreasing arsenic-induced superoxide levels in wild-type cells effectively prevented loss of scavenging activity, defenestration, and junctional PECAM-1 expression. We used gp91ds-tat, an inhibitory peptide targeting Nox2 interaction with p47phox, to implicate the Nox2-based oxidase as being the central mediator of the oxidant response to arsenic. In contrast to the effects of the scrambled-tat peptide, in which the active targeting sequence in gp91ds-tat is rearranged (28), gp91ds-tat was completely effective in protecting the SECs. Final proof of the central role of the SEC Nox2-based oxidase in arsenic signaling was provided by the observation that preventing Rac1-GTPase activity provided protection from arsenic-stimulated defenestration. Rac1-GTPase is another essential component of the Nox2-based oxidase that provides an axis for enzyme stimulation in response to a number of endogenous ligands and environmental stimulants (24, 25). Thus, the data are consistent with SEC Nox2-based oxidase directly contributing to endothelial dysfunction and suggest that this oxidase is the dominant isozyme for arsenic-stimulated superoxide generation and capillarization.

The data provide little support for a role of the other prevalent endothelial-expressed isozyme, Nox4-based oxidase, in the response to arsenic, because this isoform does not require p47phox and thus should not be affected by either the p47phox knockout or gp91ds-tat (28, 34). There is a single in vitro report indicating that overexpression of constitutively active type 1 VEGF receptor in an immortalized SEC line resulted in a 6-fold induction of Noxl, which increased apoptosis (35). However, the cell line was not well characterized as retaining SEC phenotype, and Noxl is generally expressed at low levels in endothelial cells (25, 28, 34). The in vivo data in the current study do not rule out contributions of the Nox2 oxidase in other liver cells, because stellate and Kupffer cells, as well as hepatocytes, express the Nox2 anchor (36, 37). Nonetheless, the ex vivo data confirm the...
necessary and sufficient role for SEC Nox2-based oxidase in both capillarization and functional loss, and additional oxidants from other liver cells would only add to this pathologic change in vivo.

Arsenic-stimulated superoxide generation may promote defenestration and capillarization by ROS-mediated signaling or quenching NO that is required for maintaining the fenestrated SEC phenotype. The data in Figure 4D suggest that H₂O₂ is effective in promoting SEC defenestration and thus may be the second messenger for these arsenic actions in the SECs. However, fenestrated endothelium is found in tissues constitutively expressing high levels of VEGF and VEGF-stimulated NO (38). DeLeve et al. demonstrated that the SEC phenotype was maintained by paracrine stimulation through hepatocyte- and stellate cell-derived VEGF-stimulated NO production in either the stellate cells or the SECs (15). In reciprocal regulation, the SEC NO suppresses stellate cell activation and collagen expression that facilitates fibrosis (16). Loss of NO contributes to pathogenic angiogenesis, fibrosis, and portal hypertension in the liver (39). Peroxynitrite formed from the reaction of superoxide and NO has been proposed as a pathogenic mediator of liver perfusion defects caused by obesity and insulin resistance (21). Nitrosylation of protein tyrosine residues is a marker of peroxynitrite formation, and the observation that arsenite failed to increase protein nitrosylation in p47phox knockout mice (Figure 5) suggests that stimulation of superoxide generation and peroxynitrite formation is a primary mechanism for arsenic-induced remodeling of the liver vasculature and impaired function in the sinusoids. The data do not discriminate, however, between the significance of superoxide depletion of regulatory NO or peroxynitrite-mediated signaling to arsenic-stimulated SEC capillarization. Nonetheless, the fact that H₂O₂ is sufficient to reduce porosity suggests that both loss of NO and peroxynitrite formation are secondary mechanisms in arsenic-stimulated capillarization.

While the functional consequences of arsenic-stimulated, oxidant-dependent signaling in SECs are unique to this cell type, the initiation of this signaling may be common to endothelial cells in most vascular beds. We observed that environmental exposure to arsenic stimulates angiogenesis in Matrigel plugs and tumor xenographs in vivo (4, 40) as well as tube formation by human microvascular cells in cultured Matrigel (41). While the isoforms were not specifically identified, arsenic was found to stimulate large-vessel endothelial and smooth muscle cell NADPH oxidases (26, 27) and quench bradykinin-stimulated NO generation in aortic endothelial cells (42) or NO-dependent vasodilation in aortic rings (43). In addition, endothelial peroxynitrite formation appears to contribute to arsenic-promoted atherosclerosis in genetic mouse models (44). Thus, it is likely that the arsenic exposures in the current studies had systemic effects in most vascular beds. However, other pathological endpoints, such as atherosclerotic plaque formation, vessel wall thickening, or peripheral vascular disease, would not be expected to occur in a mouse within the 2-wk exposure period examined in the current studies. Nonetheless, the importance of the SEC- and liver-specific observations is that...
capillarization is a significant and relatively early pathogenic event. Sustained capillarization and loss of SEC scavenging may precede arsenic-promoted systemic disease or enhance deleterious systemic effects of arsenic by impairing clearance of acetylated lipids or modified proteins that are known risk factors for vascular and metabolic disease. Further studies are needed to determine whether the arsenic-induced anisodam morphological changes and loss of SEC scavenger function are initial steps in arsenic-induced vascular disease or are limited to pathogenic changes in the liver.

The finding of morphological and functional changes in livers of mice exposed to concentrations of arsenic that promote human diseases other than cancer is notable, because mice are often several orders of magnitude less sensitive than humans to the carcinogenic and lethal effects of arsenic. However, cardiovascular effects may be more sensitive disease endpoints in humans drinking the same levels of arsenic used in the current studies (1, 2, 7), and our present findings suggest that the mouse is an appropriate model for studying the etiology of arsenic-promoted disease. In addition, these studies provide valuable information regarding gene environment interactions. Hsueh et al. suggested that genetic polymorphisms in the NADPH oxidase p22 subunit may contribute to arsenic-related hypertension in Taiwan (8).

In summary, the current data support an essential role for an NADPH oxidase in a form of pathogenic vascular remodeling that can contribute to liver disease as well as to systemic hypertension and atherogenesis. The Nox2-based oxidase in SECs appears to be directly activated by environmental exposures to arsenic, and this activation is central to arsenic-induced capillarization and loss of SEC scavenging function. The apparent requirement for Ras1-GTPase activity (Figure 8) suggests that Rac1 and oxidase activation are not downstream of the target of arsenic in the endothelial cells and that peroxynitrite formation may be a pathogenic endpoint of arsenic signaling in SECs. However, future experiments are needed to identify the molecular targets on endothelial cells that initiates arsenic signaling for oxidase activation. Identifying this target may reveal important pathogenic mechanisms promoting SECs and possibly systemic endothelial dysfunction that contribute to the etiology of environmentally derived vascular diseases.

Methods
Animal exposure. Animal experiments were performed in agreement with institutional guidelines for animal safety and welfare at the University of Pittsburgh. Wild-type C57Bl/6 Tcr mouse exposures were performed as described previously (22, 23). Serial dilutions were used to prepare drinking water with sodium

Figure 6
Arsenic-stimulated superoxide generation is inhibited by tempol and gp91 ds-tat peptide. (A) Primary SECs isolated from mice were pre-loaded with 5 μM dihydroethidium for 10 min prior to a 30-min arsenite exposure. Cells were fixed and imaged for hydroethidium (HE; red) fluorescence and DAPI (blue) stained nuclei. Scale bar: 10 μm. (B) Percent (mean ± SD) positive hydroethidium staining, normalized to the percentage of positive nuclei staining (n = 4 cultures from 2 livers). (C) SECs were pre-loaded with 5 μM dihydroethidium with and without 1 mM tempol 10 min prior to a 30-min, 2.5-μM arsenite exposure and then imaged and analyzed as in B (n = 4 cultures). (D) Cells were preincubated with dihydroethidium in the presence or absence of 10 μM gp91 ds-tat (gp-tat) or scrambled-tat (sc-tat) peptide for 30 min prior to a 2.5-μM arsenite exposure (n = 6 cultures from 3 livers). In C and D, significance of differences was determined by ANOVA followed by Newman-Keuls post test. **P < 0.01, ***P < 0.001 versus control; ###P < 0.001 versus arsenite.
arsenite concentrations of 10, 50, 100, or 250 ppb. C57BL/6Ai p47-phox knockout mice (Taconic Farms) were housed under pathogen-free conditions in autoclaved microisolator cages with Alpha-dri bedding (Shepherd Specialty Papers) to reduce footpad irritation and edema. The mice were treated with 380 mg broad-spectrum sulfamethoxazole-clindamycin antibiotic per 500 ml drinking water according to the vendor’s instructions (Taconic Farms). C57BL/6 mice housed in the same manner and treated with antibiotic served as controls for the C57BL/6Ai p47-phox knockout mice. There were no observable infections during the arsenic exposures or at the time of necropsy. All water was changed 3 times per week to maintain effective concentrations of arsenite and antibiotic. Liver perfusions with collagenase, fixative, or modified medium were prepared and imaged as previously described (22, 23, 47). For quantitative immunofluorescence, 3 representative ×400 images from individual coverslips were captured by a microscopist blinded to treatments, as described previously (22, 23). The percentage of positive pixels in the 3 images was averaged to give a single value per coverslip. Values were normalized by dividing the percent thresholded area of PECAM expression by percent thresholded area of nucleus. Porosity, the percent of open space in sinusoidal vessels or cultured cells, was measured in representative ×7,500 or ×10,000 scanning EM images of vessels and cells, respectively, as described previously (22, 23, 48). Briefly, images from 3-μm-thick liver sections were captured with a JSM-6330F scanning electron microscope, and images of 10 midlobular sinusoids were prepared and imaged as previously described (22, 23, 47). For quantitative immunofluorescence, 3 representative ×400 images from individual coverslips were captured by a microscopist blinded to treatments, as described previously (22, 23). The percentage of positive pixels in the 3 images was averaged to give a single value per coverslip. Values were normalized by dividing the percent thresholded area of porosity expression by percent thresholded area of nuclei. Porosity, the percent of open space in sinusoidal vessels or cultured cells, was measured in representative ×7,500 or ×10,000 scanning EM images of vessels and cells, respectively, as described previously (22, 23, 48). Briefly, images from 3-μm-thick liver sections were captured with a JSM-6330F scanning electron microscope, and images of 10 midlobular sinusoids were prepared and imaged as previously described (22, 23, 47). For quantitative immunofluorescence, 3 representative ×400 images from individual coverslips were captured by a microscopist blinded to treatments, as described previously (22, 23, 47). There was little inter- and intraoperator variation in quantifying porosity or immunofluorescence, as evidenced by the close agreement between the values obtained in the current studies and our 2 previous studies of the effects of arsenic on the SEC (22, 23). Microscopy and quantitative imaging. At necropsy, livers were either excised and snap frozen in liquid nitrogen or perfusion fixed with glutaraldehyde in preparation for immunofluorescent analysis of proteins or scanning EM of tissue ultrastructure. Tissues for immunofluorescence and scanning EM were prepared and imaged as previously described (22, 23, 47). For quantitative immunofluorescence, 3 representative ×400 images from individual coverslips were captured by a microscopist blinded to treatments, as described previously (22, 23). The percentage of positive pixels in the 3 images was averaged to give a single value per coverslip. Values were normalized by dividing the percent thresholded area of PECAM expression by percent thresholded area of nuclei. Porosity, the percent of open space in sinusoidal vessels or cultured cells, was measured in representative ×7,500 or ×10,000 scanning EM images of vessels and cells, respectively, as described previously (22, 23, 48). Briefly, images from 3-μm-thick liver sections were captured with a JSM-6330F scanning electron microscope, and images of 10 midlobular sinusoids were prepared and imaged as previously described (22, 23, 47). For quantitative immunofluorescence, 3 representative ×400 images from individual coverslips were captured by a microscopist blinded to treatments, as described previously (22, 23, 47). There was little inter- and intraoperator variation in quantifying porosity or immunofluorescence, as evidenced by the close agreement between the values obtained in the current studies and our 2 previous studies of the effects of arsenic on the SEC (22, 23). Superoxide detection. Primary SECs were isolated and cultured as described above. Dihydroethidium (5 μM) was loaded into cells for 10 min before adding arsenite for 30 min. The cells were then fixed and stained with DRAQ5. Quantitative immunofluorescence was used to determine changes in dihydroethidium oxidation normalized to percentage of nuclear pixels, as described above. To scavenge superoxide, 1 mM tempol (Sigma-Aldrich) was added for 10 min prior to adding arsenite. To inhibit
NADPH oxidase, 10 μM of either gp91ds-tat or scrambled-tat peptide—synthesized as described previously (28)—were added to cells 30 min prior to adding arsenic. All experimental groups contained at least 6 SEC cultures with duplicate coverslips of cells from 3 separate livers.

**Modular albumin synthesis.** FITC- or biotin-labeled native or succinylated BSA was prepared as follows. Briefly, a 10-M excess of FITC (Sigma-Aldrich) or biotin-NHS (Pierce), freshly prepared in DMSO, was added into 1 ml of BSA solution (100 mg/ml in 1 M NaHCO3). The reaction was allowed to proceed at 4°C for 1 h. The reaction mixture was then either thoroughly dialyzed against PBS, to obtain labeled native BSA, or reacted with 4-25-mg aliquots of succinyl anhydride at 15-min intervals. The succinylation continued overnight at 4°C, and then the reaction mixtures were purified by dialysis. The degree of succinylation of free amino groups was estimated to be 90% by reacting the remaining NH2 groups with 2,4,6-trinitrobenzene sulfonic acid (Pierce).

**Modified albumin uptake.** To demonstrate SEC-specific uptake, 150 μg/kg of FITC-labeled BSA or succinylated BSA was injected into the mouse tail vein in 200 μl saline. After 10 min, livers were excised, fixed in 4% paraformaldehyde, and sectioned for confocal microscopic analysis. Quantitative uptake of succinylated BSA was measured in control and arsenic-exposed mice by infusing a mixture of FITC-labeled acetylated LDL. (BTI Technologies) and biotin-labeled succinylated BSA (150 mg/ml saline) into the vena cava over 3 min. Livers were then excised, snap frozen in liquid N2, and sectioned. To control for differential perfusion of liver lobes, microscopists blinded to treatment selected liver sections with equivalent levels of FITC-labeled acetylated LDL fluorescence. Total protein was extracted from these sections, and equal amounts were assayed for biotinylated albumin by immunoblotting. Likewise, cultured control SECs or SECs exposed to arsenic for 24 h were incubated with 20 μg/ml biotin-labeled succinylated BSA for 10 min, rinsed 3 times with PBS, and then extracted for total protein to determine modified albumin uptake. Biotin in the 7S-kDa BSA protein band was detected on transfer membranes using HRP-conjugated goat anti-biotin antibody (Cell Signaling) and enhanced chemiluminescence. Secondary antibodies included goat anti-rat (Invitrogen), Alexa Fluor 488-conjugated goat anti-rabbit (Invitrogen), Alexa Fluor 594-conjugated goat anti-rabbit (Invitrogen), and HRP-conjugated sheep anti-mouse (GE Healthcare). DRAQ5 was used to stain nuclei.

**Statistics.** Mice and SECs exposed to various doses of arsenic were analyzed using 1-way ANOVA followed by Dunnett’s or Newman-Keuls post test for difference between treatments. All statistical analyses were performed using GraphPad statistical software version 4.0. A P value less than 0.05 was considered significant.

**Acknowledgments.** The authors thank Simon Watkins for use of the confocal and electron microscopes and for processing of tissues and cells at the Center for Biological Imaging. We also thank Timothy Billiar for the donation of SECs and his technical assistants, Carol Meiers and Danielle Reiser, for their outstanding technical assistance in SEC isolations. This work was supported by NIHES grant ES013781 (to A. Barchowsky), NCI grant CA76541 (to D.B. Stolz), NHLBI grants HL68688 (to S. Li) and HU79207 (to P.J. Pagano), EPA STAR Fellowship FP-91554201 (to A.C. Straub), and an internal grant from the Office of the Senior Vice Chancellor for the Health Sciences, University of Pittsburgh. P.J. Pagano is the Established Investigator of the American Heart Association (AHA 0540029N).
